Abstract
Attaining optimal results in real-life scheduling is hindered by a number of problems. One such problem is dynamics of scheduling environments with breaking-down resources and hot orders coming during the schedule execution. Traditional approach to react to unexpected events occurring on the shop floor is generating a new schedule from scratch. Complete rescheduling, however, may require excessive computation time. Moreover, the recovered schedule may deviate a lot from the ongoing schedule. Some work has focused on tackling these shortcomings, but none of the existing approaches tries to substitute jobs that cannot be executed with a set of alternative jobs. This paper describes the scheduling model suitable for dealing with unforeseen events using the possibility of alternative processes and states the future goals.

Introduction
Scheduling, the aim of which is to allocate scarce resources to activities in order to optimize certain objectives, has been frequently addressed in the past decades. Developing a detailed schedule in manufacturing environment helps maintain efficiency and control of operations.

In the real world, however, manufacturing systems face uncertainty owing to unforeseen events occurring on the shop floor. Machines break down, operations take longer than anticipated, personnel do not perform as expected, urgent orders arrive, others are canceled, etc. These disturbances may bring inconsistencies into the ongoing schedule. If the ongoing schedule becomes infeasible, the simple approach is to collect the data from the shop floor when the disruption occurs and to generate a new schedule from scratch. Because most of the scheduling problems are NP-hard, complete rescheduling usually involves prohibitive computation time and an excessive deviation of the recovered schedule from the original schedule.

To avoid the problems of rescheduling from scratch, reactive scheduling, which may be conceived as the continuous correction of precomputed predictive schedules, is becoming more and more important. Reactive scheduling is distinguished from predictive scheduling mainly by its on-line nature and associated real-time execution requirements. The schedule update must be accomplished before the running schedule becomes invalid, and this time window may be very short in complex scheduling environments.

Several novel sophisticated methods attempt to cope with the shortcomings of complete rescheduling, e.g., by rescheduling only the activities somehow affected by the disturbance. To the best of our knowledge, however, none of the existing approaches tries to replace some activities by a set of alternative activities (using other available resources) to achieve the same goal.

In this paper we propose a model suitable for development of algorithms for modifying a schedule to accommodate disturbances, such as a machine breakdown, using the possibility of alternative processes, i.e., to re-plan the influenced part of the schedule.

Related Work
The approaches how to tackle dynamics of the scheduling environment can be divided basically into two branches according to whether or not the predictive schedule is computed before the execution starts (Vieira, Herrmann, and Lin 2003). If the predictive schedule is not computed beforehand and individual activities are assigned to resources pursuant to some so called dispatching rules during the execution, we talk about completely reactive scheduling or on-line scheduling. This strategy is suitable for very dynamic environments, where it is not known in advance which activities it will be necessary to process. On the other hand, it is obvious that this approach hardly ever leads to an optimal or near-optimal schedule.

If the schedule is crafted beforehand and then updated during its execution, it is referred to as predictive-reactive scheduling. When correcting the ongoing schedule in response to changes within the environment, the aim is usually to minimize the schedule modification. The motivation for minimizing the alteration of the schedule is that every aberration may lead to deterioration in the performance owing to affecting other planning activities based upon the original schedule. Similarity of two schedules may be formally defined for example as a minimal perturbation problem (Barták, Muller, and Rudová 2003).

There is an extensive literature on rescheduling (Ouelhadj and Petrovic 2009; Raheja and Subramaniam 2002). First,
the heuristic-based approaches do not guarantee finding an optimal solution, but they respond in a short time. The simplest schedule-repair technique is the right shift rescheduling (Abumaizar and Svestka 1997), which shifts the operations globally to the right on the time axis in order to cope with disruptions. This may lead to schedules of very bad quality.

Another simple heuristic is affected operation rescheduling (Smith 1995), also referred to as partial schedule repair, the essence of which is to reschedule only the operations directly and indirectly affected by the disruption in order to minimize the deviation from the initial schedule.

Better schedules to the detriment of computational efficiency may be attained by using meta-heuristics such as simulated annealing, genetic algorithms, tabu search, and iterative flattening search (Oddi et al. 2007). These high level heuristics guide local search methods to escape from local optima by occasional accepting worse solutions or by generating better initial solutions for local probing in some sophisticated way.

Some techniques from the field of artificial intelligence and knowledge-based systems are also applied in rescheduling, namely case-based reasoning (Cunningham and Smyth 1997), fuzzy logic (Ramkumar, Tamilarasi, and Devi 2011), and neural networks (Jain and Meenan 1998). Another approach, which is rather an independent branch, is multi-agent based architectures (Zhang et al. 2011). Multi-agent systems seem to be the most promising approach, but the coordination among the agents is hard to achieve.

The attempts to absorb certain amount of uncertainty based on the past executions of schedules is considered in another strategy, usually referred to as robust proactive scheduling. One such example is a model and an algorithm generating a predictive schedule of production workflows that is (proactively) robust with regard to so called immediate events, which include breakdown of a workstation and faulty termination of a workflow execution (Dulai and Werner-Stark 2015). The robustness is attained by shifting activities (traditional introducing or enlarging gaps on resources) based on the probabilities of resource failures, which are estimated according to previous experiences. The drawback of the algorithm is the assumption that every resource failure is only temporary, and the time for how long the resource is unavailable in case of its failure is known in advance.

While there is a great amount of work devoted to planning with time and resources and to integrating planning and scheduling techniques, to the best of our knowledge, there is no research carried out aiming at the possibility of re-planning in the field of predictive-reactive scheduling.

**Scheduling Model Description**

The scheduling model we work with is taken from the FlowOpt system (Barták et al. 2012), which contains a tool for designing and editing manufacturing workflows. Workflow in general may be understood as a scheme of performing some complex process, itemized into simpler processes and relationships among them. Manufacturing workflow is then an outline how to obtain a desired product.

In order to make editing of workflows easier, the workflows in our model match up the structure of Nested Temporal Networks with Alternatives (Barták and Čepák 2007), where the nodes of a network correspond to the tasks of a workflow. The tasks decompose into other tasks, referred to as their children. There are two types of decomposition: parallel and alternative. The tasks that do not decompose further (i.e., leaves) are called primitive tasks. The primitive tasks correspond to activities (or operations) and are associated with some additional parameters, namely start, end, and duration.

An example of a workflow and its decomposition tree are depicted in Figures 1 and 2. It contains eight primitive tasks (activities), three parallel tasks, and two alternative tasks.

The workflows as described define a number of feasible processes. A process is a subset of tasks selected to be processed. While a parallel task requires all its children to be processed, an alternative task requires exactly one of its children to be processed. If an arbitrary task is not in a process, none of its offspring is in the process either. Hence, to ensure that an instance of a workflow is actually processed, its root task has to be in the selected process. An example of a process is depicted in Figure 3.

To introduce some restrictions in terms of occurrences of tasks in the process and their time data, a pair of tasks can be bound by a constraint. Temporal constraints include precesses (one task has to be accomplished before the execution of another task starts), and synchronizations (one task has to
Formally, schedule lateness penalty. An instance of a workflow is referred to as an \( n \) nature a particular product. If a user wants must be allocated to exactly one resource (selected resource). which the activity can be processed (resource group), and in than one activity at a time. This limitation is often referred to unary, which means that each resource may perform no more time of its latest child.

In Figure 1, there is one equivalence constraint enforcing that a tube and a rod are both either bought or made. The other constraint (synchronization) ensures that the activities "cutting tube" and "cutting rod" start at the same time.

Besides these constraints added by a user, which are referred to as custom constraints, there are some implicit constraints arising from the hierarchical structure of tasks. For example, the start time of a task equals the start time of its earliest child, and the end time of the task equals the end time of its latest child.

Activities are processed on resources. All resources are unary, which means that each resource may perform no more than one activity at a time. This limitation is often referred to as a resource constraint and belongs to the mentioned implicit constraints. Each activity is specified by a set of resources on which the activity can be processed (resource group), and in the resulting schedule, each activity in the selected process must be allocated to exactly one resource (selected resource).

Note that workflow is only a guideline how to manufacture a particular product. If a user wants \( n \) such products, \( n \) instances of the corresponding workflow are inserted into the model. An instance of a workflow is referred to as an order. It contains some additional data, such as due date and lateness penalty.

Finally, a resulting schedule is feasible if all custom as well as implicit constraints are satisfied.

**Scheduling Problem**

Formally, schedule \( S \) is a triplet of three sets: \( \text{Tasks}, \text{Constraints}, \) and \( \text{Resources} \).

**Tasks** Tasks match up a forest structure. Therefore, every task \( T \) either has a parent, i.e., \( \exists P \in \text{Tasks} : \text{parent}(T) = P \), or is a root, i.e., \( \text{parent}(T) = \text{null} \).

- \( \text{subtasks}(T) = \{C \in \text{Tasks} | \text{parent}(C) = T \} \)
- \( \text{Roots} = \{R \in \text{Tasks} | \text{parent}(R) = \text{null} \} \)

There are three types of tasks: parallel, alternative, and primitive tasks.

- \( \text{Tasks} = \text{Parallel} \cup \text{Alternative} \cup \text{Primitive} \)
- \( \forall T \in \text{Parallel} \cup \text{Alternative} : \text{subtasks}(T) \neq \emptyset \)
- \( \forall T \in \text{Primitive} : \text{subtasks}(T) = \emptyset \)

Let process \( P \subseteq \text{Tasks} \) be the set of tasks selected to be processed. Making the process feasible introduces the following constraints:

- \( T \in P \cap \text{Parallel} : \text{subtasks}(T) \subseteq P \)
- \( T \in P \cap \text{Alternative} : |\text{subtasks}(T) \cap P| = 1 \)
- \( T \notin P : \text{subtasks}(T) \cap P = \emptyset \)

Let \( S_i \) and \( E_i \) denote the start time and end time, respectively, of task \( T_i \). Each activity corresponding to the primitive task \( T_i \) is specified by the duration \( D_i \). Then the time data are computed as follows:

- \( \forall T_i \in P \cap \text{Primitive} : S_i + D_i = E_i \)
- \( \forall T_i \in P \cap (\text{Parallel} \cup \text{Alternative}) : S_i = \min\{S_j | T_j \in \text{subtasks}(T_i) \cap P\} \)
- \( E_i = \max\{E_j | T_j \in \text{subtasks}(T_i) \cap P\} \)

**Constraints** There are two basic types of constraints: temporal, and logical. Temporal constraints restrict mutual position in time of two distinct activities. We take into consideration precedence and synchronization constraints, the semantics of which is as follows:

- \( (i \to j) : T_i, T_j \in P \Rightarrow E_i \leq S_j \)
- \( (i \leq j) : T_i, T_j \in P \Rightarrow S_i = S_j \)
- \( (i \leq \neq j) : T_i, T_j \in P \Rightarrow S_i = E_j \)
- \( (i \neq \leq j) : T_i, T_j \in P \Rightarrow E_i = S_j \)
- \( (i \neq \leq \neq j) : T_i, T_j \in P \Rightarrow E_i = E_j \)

Logical constraints are of three types: implications, equivalences, and mutexes. The semantics of the constraints is such:

- \( (i \Rightarrow j) : T_i \in P \Rightarrow T_j \in P \)
- \( (i \iff j) : T_i \in P \iff T_j \in P \)
- \( (i \text{mutex} j) : T_i \notin P \vee T_j \notin P \)

**Resources** Let \( T \in \text{Primitive} \), then the set of resources that may process the primitive task \( T \) is denoted \( \text{Resources}(T) \). The set \( \text{Resources}(T) \) is often referred to as a resource group.

Each activity to be processed needs to be allocated to exactly one resource from its resource group. Let \( T \in \text{Primitive} \), then a resource \( R \in \text{Resources}(T) \) is selected if resource \( R \) is scheduled to process the primitive task \( T \), which we denote \( \text{SelectedResource}(T) = R \).

Each primitive task that is selected to the process \( P \) must have a selected resource to make a schedule feasible. Formally:

\[ \forall T \in P \cap \text{Primitive} : \text{SelectedResource}(T) \neq \text{null} \]

All resources in a schedule are unary, which means that they cannot execute more tasks simultaneously. Therefore,
in a feasible schedule for all selected primitive tasks $T_i \neq T_j$
the following holds:

\[
SelectedResource(T_i) = SelectedResource(T_j) \\
\Rightarrow E_i \leq S_j \lor E_j \leq S_i
\]

**Schedule**

A schedule $S$ (sometimes referred to as a resulting schedule or a solution) is acquired by determining the set $P$, and allocating the primitive tasks from $P$ in time and on resources. Allocation in time means assigning particular values to the variables $S_i$ and $E_i$ for each $T_i \in P$. Allocation on resources means selecting a particular resource ($SelectedResource(T)$) from the resource group ($Resources(T)$) of each task $T \in P \cap Primitive$.

To make a schedule feasible, the allocation must be conducted in such a way that all the mentioned constraints in the problem are satisfied.

**Rescheduling Problem**

The problem we actually deal with is that we are given a particular instance of the scheduling problem along with a feasible schedule, and also with a change in the problem specification. The aim is to find another schedule that is feasible in terms of the new problem definition. The feasible schedule we are given is referred to as an original schedule or an ongoing schedule.

Formally, let $R = (Pr_0, Sch_0, \delta^+, \delta^-)$ be a rescheduling problem, which is given by the original scheduling problem $Pr_0$, the original feasible schedule $Sch_0$, elements $\delta^+$ to be added to the problem $Pr_0$, and elements $\delta^-$ to be removed from the problem $Pr_0$. New scheduling problem $Pr_1$ is then $Pr_0 \cup \delta^+ \setminus \delta^-$. The task of the rescheduling problem $R$ is then to find a schedule $Sch_1$ for problem $Pr_1$, the quality of which is measured with respect to the original schedule $Sch_0$.

The way the scheduling problem can be modified depends on the disturbance. In case of a resource failure, we are given a resource that cannot be used (from a certain time point) while the set of orders remains unchanged, therefore $\delta^+ = \emptyset$ and $\delta^- = \text{the broken down resource}$.

Another example is an urgent order arrival, which is a disturbance where an order (a set of workflow instances) is added into the model, and the aim is to update the ongoing schedule in such a way that the added order is accomplished as early as possible. In this case $\delta^+$ is the new order (including constraints among new tasks) and $\delta^- = \emptyset$.

As explained in the introduction, regardless of what the optimization objective of the original schedule is, it seems to be wise to modify the schedule in such a way that the new schedule is as similar to the original one as possible. For this purpose we need to evaluate the modification distance.

Let $P_1$ denote the selected process $P$ in the schedule $Sch_2$, and $S^+_i$ denote the start time of task $T_i$ in schedule $Sch_2$. Then, apart from computation time, we take into account the following distance functions:

\[
f_0 = |(T \in P_1 \setminus P_0)| + |(T \in P_0 \setminus P_1)|
\]

\[
f_1 = \sum_{T_i \in P_0 \cap P_1 \cap Primitive} |S^+_i - S^+_0|
\]

\[
f_2 = |\{T_i \in P_0 \cap P_1 \cap Primitive \mid S^+_i \neq S^+_0\}|
\]

\[
f_3 = \max_{T_i \in P_0 \cap P_1 \cap Primitive} |S^+_i - S^+_0|
\]

In words, $f_0$ is the number of different tasks in the schedules, $f_1$ measures the total sum of time shifts of activities, $f_2$ counts the number of shifted activities, and $f_3$ is the biggest time shift of an activity. There are other conceivable distance functions, but we concentrate on these ones.

**Current Work**

Our recent work (Barták and Vlk 2015) proposes two methods to handle a resource failure occurring on the shop floor during the schedule execution. The first method, *Right Shift Affected*, takes the activities that were to be processed on a broken machine, reallocates them, and then it keeps repairing violated constraints until it gets a feasible schedule. This approach is suitable when it is desired to move as few activities as possible, that is, minimizing the distance function $f_2$.

The second method, which is aimed at shifting activities by a short time distance regardless of the number of moved activities (that is, minimizing the distance functions $f_1$ and $f_3$), is called *STN-recovery*. The routine deallocates a subset of activities and then it allocates the activities again through integrating techniques from the field of constraint programming, namely *Conflict-Directed Backjumping with Backmarking* (Kondrak and Van Beek 1997). Before the allocation process, the search space is suitably pruned based on the values from the original schedule, which is another thing that seems to be neglected in the related literature.

The shortcoming of both the algorithms is that they neglect the posibility of alternative processes, which in practice may lead to a schedule recovery at a blow. Moreover, if the ongoing schedule is not recoverable, the algorithms are not able to securely report it and terminate.

**Future Plans**

We are currently developing algorithms under the hierarchical model described, where, in response to unexpected events, the intention is not only to modify the allocation of activities of the selected process, but to replace tasks in the process by other tasks that are not in the process, i.e., to re-plan some (ideally the smallest necessary, hence the motivation for the distance function $f_0$) subset of the schedule.

The first algorithm to try will work as follows. First, find the feasible process from all the orders in the schedule top-down, preferring the branches from the original schedule whenever possible. Second, after the process is selected, allocate activities from the process in time and on resources. If the second step fails, go back to the first step. Iterate until the schedule is found. For the second step, the crucial part of the STN-recovery algorithm mentioned above may be employed.
One natural improvement might be trying to allocate an activity straightaway when the corresponding primitive task is considered to be selected to the process. If the activity is successfully allocated, the searching for the process proceeds, otherwise it backtracks for alternatives.

However, our main effort will be made towards updating the schedule as locally as possible. If a resource suddenly becomes unavailable, it may suffice to merely replace the affected activities by alternatives that are just one level (one task decomposition) from the affected activities. It follows that the process should not be discarded and ought again top-down as described above, but it should be explored in a bottom-up fashion (from the primitive tasks upwards). The main difficulty of this approach are the logical constraints that must be propagated whenever the membership of a task in the process is being flipped.

In further future, the target is to extend the model of Nested Temporal Networks with Alternatives by recursion, and to suggest algorithms for this model. The recursion will bring the full power of planning, i.e., the possibility to generate tasks according to a given target. The main inspiration comes from the Hierarchical Task Networks (Nau et al. 2003). We will try modeling problems by attribute grammars, where modeling relations among attributes will be realized by constraint satisfaction problem rather than traditional semantic rules (Barták 2016).
